Abstract

The transfer matrix method is often used to calculate the input impedance of woodwind instruments but it ignores the possible influence of the radiated sound from toneholes on other open holes. In this paper, a method is proposed to account for external tonehole interactions. It is found that the external tonehole interactions increase the amount of radiated energy, reduce slightly the lower resonance frequencies, and modify significantly the response near and above the tonehole lattice cutoff frequency.

The results of simulations with the Finite Element Method, as well as experimental measurements, are presented and compared to the calculation with the method presented in this paper, confirming that the external tonehole interactions play a significant role in woodwind instrument.

1 Introduction

A method to accurately and efficiently estimate the input impedance and resonance frequencies of woodwind instruments is of primary importance. The Transfer-Matrix Method (TMM) is typically used for this purpose (see e.g. Plitnik and Strong [18], Caussé et al. [3], Keefe [12]), because of its simplicity and efficiency. This method ignores internal interactions due to the coupling between the evanescent modes of nearby discontinuities as well as external interactions, which exists because the radiation impedance of each open tonehole is influenced by the radiation of sound from other toneholes. The problem of the response of woodwind instruments with external tonehole interactions was stated in a complete form by Leppington [15] and a method of solution was proposed by Kergomard [13], using the mutual radiation impedance proposed by Pritchard [19]. This method is based on the TMM for internal propagation with modified open tonehole radiation impedances to account

for interactions (referred to as TMMI). Preliminary experimental results were obtained by Springer [20] for the case of holes spaced far apart in a pipe. No other validation of the method has been proposed.

In this paper, we investigate the effect of external tonehole interactions in woodwind instruments with the TMMI. The first goal is to determine the validity of the method by comparing the results of TMMI calculations with Finite Element Method (FEM) simulations and with measurements. We also compare these results with TMM calculations to show that most of the discrepancies are explained by the external interactions.

The second goal is to apply the proposed TMMI method to the case of woodwind instruments in order to determine the importance of the effect on their acoustical properties and to judge whether or not it is necessary to account for those interactions when calculating the input impedance of woodwind instruments for design purposes.

The theory of the TMM and TMMI, as well as the details of the FEM, are reviewed in the next section. This is followed by the presentation of the results for a tube with a regular array of holes (Sec. 3), then results for a saxophone and a clarinet (Sec. 4) and finally the conclusions (Sec. 5).

2 Background

2.1 The TMM

The transfer matrix method (TMM) provides an efficient means for calculating the input impedance of a hypothetical air column [18, 3, 12]. With the TMM, a geometrical structure is approximated by a sequence of one-dimensional segments, such as cylinders, cones, and closed or open toneholes, and each segment is represented by a transfer matrix (TM) that relates its input to output frequency-domain quantities of pressure (P) and volume velocity (U). The multiplication of these matrices yields a single matrix which must then be multiplied by an appropriate radiation impedance at its output. That is:

$$\begin{bmatrix} P_{in} \\ U_{in} \end{bmatrix} = \left(\prod_{i=1}^n \mathbf{T}_i \right) \begin{bmatrix} Z_{rad} U_{out} \\ U_{out} \end{bmatrix}, \quad (1)$$

where Z_{rad} is the radiation impedance and U_{out} can be set arbitrarily. The input impedance is then calculated as $Z_{in} = P_{in}/U_{in}$.

The theoretical expression of the transfer matrix of a cylinder is:

$$\mathbf{T}_{cyl} = \begin{bmatrix} \cosh(\Gamma L) & Z_0 \sinh(\Gamma L) \\ \sinh(\Gamma L)/Z_0 & \cosh(\Gamma L) \end{bmatrix}, \quad (2)$$

where $Z_0 = \rho c / \pi a^2$, $\Gamma = j\omega/c + (1+j)\alpha$ is the complex propagation constant, ρ is the air density, c the speed of sound, and ω the angular frequency. Losses are represented by α , which depends on the radius a of the cylindrical pipe and varies with the

square root of the lossless wavenumber $k = \omega/c$:

$$\alpha = (CST/a)\sqrt{k}, \quad (3)$$

where CST is a constant that depends of the properties of air:

$$CST = \sqrt{\ell_v/2}(1 + (\gamma - 1)/\sqrt{\text{Pr}}), \quad (4)$$

$\ell_v = \mu/\rho c$ is the characteristic length of viscous effects, μ is the dynamic viscosity, Pr the Prandtl number and γ the ratio of specific heats.

The transfer matrix of a conical waveguide is (see Chaigne and Kergomard [4]):

$$\mathbf{T}_{cone} = \begin{bmatrix} (a_2/a_1) \cos(k_c L) - \sin(k_c L)/kx_1 & jZ_c \sin(k_c L) \\ Z_c^{-1} [j(1 + (k^2 x_1 x_2)^{-1}) \sin(k_c L) + (x_1^{-1} - x_2^{-1}) \cos(k_c L)/jk] & (a_1/a_2) \cos(k_c L) + \sin(k_c L)/kx_2 \end{bmatrix}, \quad (5)$$

where a_1 and a_2 are the radii at the input and output planes, respectively, and x_1 and x_2 are the distances between the apex of the cone and the input and output planes, $Z_c = \rho c/(\pi a_1 a_2)$ and $k_c = -j\Gamma$ is the complex wavenumber. In this case, losses are evaluated at the equivalent radius [4]:

$$a_{eq} = L \frac{a_1}{x_1} \frac{1}{\ln(1 + L/x_1)}. \quad (6)$$

The transfer matrix of the tonehole is defined as:

$$\mathbf{T}_{hole} = \begin{bmatrix} 1 + Z_a/2 & Z_a(1 + Z_a/4Z_s) \\ 1/Z_s & 1 + Z_a/2 \end{bmatrix} \quad (7)$$

where Z_a is the series impedance and Z_s the shunt impedance. These impedances have different values in the open and closed state. The calculation of these impedances has been the subject of many articles (Nederveen et al. [17], Dubos et al. [8], Dalmont et al. [7], Lefebvre and Scavone [14]) and the reader is referred to those papers for the appropriate formulas.

2.2 The TMMI

The radiation impedance of each tonehole on a woodwind instrument is influenced by the sound radiated from other holes. A method of solution to account for such interactions was proposed by Kergomard [13]. It can be used for any bore shape by making use of the classical TMM with modifications for the matrices located between open toneholes. It gives identical results to the TMM if interactions are neglected (by specifying null mutual radiation impedances). That is, the geometry is discretized

Figure 1: Diagram of the flow contributions in Eq. (9).

identically, with both closed tonehole and open tonehole series impedance terms represented as in the TMM.

We assume an instrument with N openings (embouchure hole, toneholes, open end), where the indices of the openings range from $n = 1$ to N . The pressure P_n inside the instrument at opening n is related to the acoustic flows U_n radiating out of holes n by the following matrix relationship:

$$\mathbf{P} = \mathcal{Z}\mathbf{U}, \quad (8)$$

where we define the vector \mathbf{P} of the pressures P_n and the vector \mathbf{U} of the flow rates U_n . \mathcal{Z} is the radiation impedance matrix, which includes the effect of external interactions. The precise values of the different elements are difficult to determine. The self radiation impedances are the diagonal elements. The validity of this expression comes directly from the integral form of the Helmholtz equation if the Green function is chosen to satisfy the Neumann boundary conditions on the tube (see e.g. Eq. (7.1.17) in Morse and Ingard [16], see also Leppington [15]). As a consequence, the equations used by Keefe [11] are erroneous (see Eqs. A1a to A2b). The content of this matrix is explained in Sec. 2.2.2.

An alternative equation relating the pressures and flows due to propagation inside the instrument can be derived by assuming conservation of acoustic flow at each opening n . As illustrated in Fig. 1, the sum of the flow U_n radiating out of the tonehole, the flow U_n^{right} entering the tonehole section on the right, and the flow U_n^{left} entering the tonehole section on the left is equal to the flow source U_n^s (which is discussed hereafter). This flow conservation equation can be written as:

$$U_n^s = U_n + U_n^{left} + U_n^{right}, \quad (9)$$

where we note that the flow on the left is defined in the reverse direction.

This equation can be written in a matrix form as:

$$\mathbf{U}^s = \mathbf{U} + \mathbf{U}^{left} + \mathbf{U}^{right}, \quad (10)$$

where \mathbf{U}^s is the flow source vector.

The sum of the left and right internal flows for each section is related to the pressures:

$$\mathbf{U}^{left} + \mathbf{U}^{right} = \mathbb{Y}\mathbf{P}, \quad (11)$$

where \mathbb{Y} is the admittance matrix, which is described in Sec. 2.2.3.

By combining Eqs. (8), (10) and (11), we obtain the solution:

$$\mathbf{U} = (\mathbb{I} + \mathbb{Y}\mathbb{Z})^{-1}\mathbf{U}^s, \quad (12)$$

where \mathbb{I} is the identity matrix.

2.2.1 Source Vector of Flow Rates \mathbf{U}^s

For such a calculation, the flow-source vector \mathbf{U}^s needs to be known. Generally speaking, the reader can imagine a small loudspeaker located inside the pipe at the abscissa of each hole, providing a flow rate U_n^s . Clearly the resonator of a musical instrument is passive and such sources do not exist. All transfer functions between two acoustic quantities at every point in the space of the passive system are fully determined and the unique problem is the choice of a reference. A solution is to use as a reference the flow rate on the left at the first tonehole of the instrument (from the part of the instrument that does not have any open holes), $-U_1^{left}$. In the absence of an active source, Eq. (10) for this hole becomes:

$$-U_1^{left} = U_1 + U_1^{right}.$$

Thus, we can write $U_1^s = -U_1^{left}$ and replace Eq. (10) by the following:

$$U_1^s = U_1 + U_1^{right}. \quad (13)$$

Otherwise $U_n^s = 0$ for $n \neq 1$. In this way, we can compute all quantities with respect to U_1^s , i.e. the ratio of all quantities to U_1^s . The input impedance can be easily deduced from the knowledge of U_1^s and P_1 , the ratio U_1^s/P_1 being the input admittance Y^{up} of the part of the system with open toneholes. Therefore the input impedance is classically computed by projecting the impedance $1/Y^{up}$ at the input of the instrument, or by using a transfer matrix relationship. Then all quantities can be calculated with respect to the input flow rate U_0^{right} if necessary, where the index 0 refers to quantities at the input plane of the system.

For reed instruments, this quantity is related to the input pressure by a time-domain nonlinear characteristic.¹

¹For flute-like instruments, it should be possible to choose the flow rate U_1 exiting from the mouthpiece, which is the first open hole, as a source. However a complete nonlinear model needs to consider a pressure-difference source (i.e. a force source) near the edge, and it is necessary to add an equation in order to compute the flow rates radiating from the holes with respect to this source.

2.2.2 Radiation Impedance Matrix \mathbb{Z}

The self-radiation impedances Z_{nn} are approximately known (see e.g. Dalmont and Nederveen [6]). On the other hand, the mutual radiation impedance Z_{nm} (when $n \neq m$) is, in its simplest form (see Pritchard [19, Eq. (17)]):

$$Z_{nm} = \Re(Z_{nn}) \frac{e^{-jkd_{nm}}}{kd_{nm}} = jk\rho c \frac{e^{-jkd_{nm}}}{4\pi d_{nm}}, \quad (14)$$

where d_{nm} is the distance between toneholes n and m . With this formula, it is assumed that a hole acts as a monopole. More closely spaced toneholes have a larger mutual radiation impedance. As the mutual impedance is complex, both reactive and dissipative effects are expected.

Therefore, the impedance matrix \mathbb{Z} is a full matrix. The mutual impedance may be neglected by using a diagonal matrix \mathbb{D} with self impedance only, in which case the results are identical to those of the TMM.

2.2.3 Admittance Matrix \mathbb{Y}

The propagation of planar sound waves between two toneholes 1 and 2 can be described by classical transfer matrices:

$$\begin{bmatrix} P_n \\ U_n^{right} \end{bmatrix} = \begin{bmatrix} A_n & B_n \\ C_n & D_n \end{bmatrix} \begin{bmatrix} P_{n+1} \\ -U_{n+1}^{left} \end{bmatrix}, \quad (15)$$

where the transfer matrix is the multiplication of the transfer matrices of each segment located between the two open toneholes, including any closed toneholes. The series impedances of the open toneholes can be accounted for by including them in the transfer matrix, one-half on each side.

This matrix can be written in the form of an admittance matrix:

$$\begin{bmatrix} U_n^{right} \\ U_{n+1}^{left} \end{bmatrix} = \begin{bmatrix} Y_n & Y_{\mu,n} \\ Y_{\mu,n} & Y'_n \end{bmatrix} \begin{bmatrix} P_n \\ P_{n+1} \end{bmatrix}, \quad (16)$$

where the flow U_{n+1}^{left} is defined in the opposite direction. The parameters of this matrix are related to those of a classical transfer matrix: $Y_n = D_n/B_n$, $Y'_n = A_n/B_n$ and $Y_{\mu,n} = -1/B_n$, which assumes that $A_n D_n - B_n C_n = 1$, the condition for reciprocity. The right and left flows at one tonehole section n become:

$$U_n^{right} = Y_n P_n + Y_{\mu,n} P_{n+1} \quad (17)$$

and

$$U_n^{left} = Y_{\mu,n-1} P_{n-1} + Y'_{n-1} P_n \quad (18)$$

Thus, Eq. (9) can be expanded to:

$$U_n^s = U_n + Y_{\mu,n-1}P_{n-1} + (Y'_{n-1} + Y_n)P_n + Y_{\mu,n}P_{n+1}. \quad (19)$$

The coefficients of this equation define the admittance matrix \mathbb{Y} , which is tridiagonal. The first and last equations have to be modified because there is either no previous opening or no next opening. The last opening is located at the far end of the instrument, so that $U_N^{right} = 0$ and Eq. (19) becomes simply:

$$U_N^s = U_N + Y_{\mu,N-1}P_{N-1} + Y'_{N-1}P_N, \quad (20)$$

where U_N is the flow rate radiated at the end of the tube.

For the first opening, we use Eq. (13), where we can set U_1^s , the first entry of the flow source vector, to any value. Then, using Eq. (12), solving the problem gives the flow vector \mathbf{U} . The pressure vector \mathbf{P} can be calculated with Eq. (8).

2.3 Finite Element Calculations

The evaluation of the input impedance of woodwind instruments using the FEM involves constructing a 3D model of the air column surrounded by a radiation sphere and the solution of the Helmholtz equation for a number of selected frequencies. The body of the instrument itself is considered to be rigid. The mesh occupies the volume inside and outside the instrument. Curved third-order Lagrange elements are used.

The input impedance (or reflectance) is evaluated from the FEM solution by evaluating the relationship of pressure and volume flow (or traveling-wave components of pressure) at the input plane of the system. The surrounding spherical radiation domain uses a second-order non-reflecting spherical boundary condition on its surface, as described by Bayliss et al. [1]. Further discussion on this topic can be found in Tsynkov [21] and Givoli and Neta [9].

Thermoviscous boundary layer losses may be approximated with a special boundary condition such as presented by Cremer [5] and, more recently, Bossart et al. [2] or Kampinga et al. [10]. The boundary condition can be written as a specific acoustic admittance:

$$Y_{wall} = -\frac{v_n}{p} = \frac{1}{\rho c} \sqrt{jk\ell_v} \left[\sin^2 \theta + (\gamma - 1)/\sqrt{\text{Pr}} \right], \quad (21)$$

where v_n is the normal velocity on the boundary and θ is the angle of incidence of the plane wave. The angle of incidence may be calculated from $\cos \theta = \hat{n} \cdot \hat{v}/\|\hat{v}\|$, where the normal vector \hat{n} is of unit length. This is solved iteratively. The lossless problem is solved first, then the admittance on the boundary is calculated from the normal velocity of the solution and the problem is solved again. This is repeated until convergence is found.

The properties of air at 25 °C are used for all the simulation cases. See Caussé et al. [3] for the equations used to calculate those values.

Figure 2: The mesh of a pipe with 10 open toneholes.

The reflectance $R(f) = p_-/p_+$ (ratio of the reflected to incident pressure) is obtained from the simulation results. A cylindrical segment is added before the input plane of the object under study. The pressures p_a and p_b at two points on the centerline of this cylindrical segment, at distances a and b from the input plane, are extracted and the reflectance is calculated as:

$$R = \frac{e^{-\Gamma b} - H_{ba}e^{-\Gamma a}}{H_{ba}e^{\Gamma a} - e^{\Gamma b}}, \quad (22)$$

where $H_{ba} = p_b/p_a$ is the transfer function between the two pressures and Γ is as previously defined. A singularity in this equation exists when the distance is half of the wavelength. The reduced impedance can then be calculated with $\overline{Z} = (1 + R)/(1 - R)$.

This method to calculate the reflectance was inspired by the two-microphones transfer function method of impedance measurement. It is worth mentioning that the impedance could also be calculated as $\overline{Z}_{in} = p_{in}/\rho c v_{in}$, where the pressure and velocity are extracted directly at the input plane. When validating this approach using a cylindrical pipe, it was found that the results did not match theory as well as with the two-point method.

3 Results for a Pipe with a Regular Array of Holes

External tonehole interactions have been studied experimentally by Springer [20] during an internship in Le Mans, France. The experiment involved measuring the internal pressure at the position of the holes on a tube with an array of widely spaced toneholes. The distances between the toneholes was much larger than what is found on woodwind instruments but the conclusion remains applicable to some extent. A cylindrical pipe of 4 meters length with an internal diameter of 15.3 mm was drilled with 47 holes of 8.7 mm diameter regularly separated by 8 cm. The wall thickness was 3 mm. The internal pressure was measured at the positions of hole 1, 3 and 11. The transfer functions with respect to the pressure at the first tonehole were calculated.

Figure 3: Modulus and argument of the transfer function between the internal pressure at hole 3 and 1: experimental results (solid), theoretical calculation without external interactions (TMM, dotted) and with interactions (TMMI, dashed).

Figure 4: Modulus and argument of the transfer function between the internal pressure at hole 11 and 1: experimental results (solid), theoretical calculation without external interaction (TMM, dotted) and with interaction (TMMI, dashed).

The results are shown in Figs. 3 and 4 in comparison to theoretical calculations with and without interactions.

For frequencies lower than the cutoff frequency of a tonehole lattice, the sound is exponentially attenuated inside the waveguide, whereas the external pressure is inversely proportional to distance. Therefore, the acoustic pressure coming from the outside of the toneholes located farther down an instrument becomes stronger than the pressure coming from inside the instrument. In Fig. 3, it appears that the effect of the external interactions is negligible for the 3rd tonehole because the pressure coming from inside remains important but, in Fig. 4, the internal pressure has sufficiently decayed at the 11th hole such that the external sound field dominates. The phase curve is very instructive: when interactions are ignored the phase shift is very small, indicating evanescent waves, while when interactions are taken into account, the phase variation is linear, indicating (spherical) traveling waves.

For frequencies higher than the cutoff frequency of the tonehole lattice, the internal pressure is no longer exponentially attenuated and the effect of interactions is limited to a smoothing of the response.

Figure 5: Magnitude of the reflectance (left) and equivalent length (right) of a pipe with 10 toneholes: experimental results (solid), FEM simulation results (squares), calculations with external interactions (TMMI, dotted) and calculations without interactions (TMM, dashed).

In order to understand better the impact of the existence of external interactions on the playing characteristics of woodwind instruments, the influence of the external interactions on the input impedance (or reflectance) of a pipe with an array of closely spaced toneholes was studied. The pipe was 300 mm in length, with a 12.7 mm diameter and 3.2 mm wall thickness, and was drilled with 10 holes of 9.5 mm diameter equally spaced by 15 mm. The reflectance of that pipe was obtained with the proposed calculation method and compared to simulation results with the FEM, to experimental measurements and to calculations with the classical TMM. The magnitude of the reflectance and the equivalent length are plotted on Fig. 5.

An important observation is that the FEM results closely match the experimental measurement. This significantly increases our confidence in both the FEM and the experiment. For the equivalent length, the measurement error appears to be larger, particularly for the lower frequencies (below 1000 Hz). There also seems to be a slight systematic error of a few millimeters. The calculations with the proposed method to account for external interactions clearly gives better results than the TMM. The deep minima in the magnitude of the reflectance and the large increase in equivalent length in the higher frequencies completely disappear when interactions are included. The overall shape of the curves resemble the measured and simulated ones, even though some discrepancies remain. In the lower frequencies, the magnitude of the reflectance is reduced by the external interactions, which indicates a higher radiation efficiency. In the higher frequencies, the minima in the magnitude of the reflectance is not as low as in the measurement and is not located exactly at the same frequency. Small discrepancies also exist in the equivalent length, though they appear to be on the order of the measurement errors. In the lower frequencies, the external interactions increase the equivalent length slightly compared to predictions of the TMM. The toneholes on the pipe are located very close to each other, so that the evanescent modes excited near each discontinuity interact with those of adjacent toneholes, that is, the propagation of sound between toneholes is not planar, as assumed in the proposed method. This phenomena is one likely cause of the remaining discrepancies. Another is that the model of the mutual interaction assumes that each tonehole is a monopole. In spite of those simplifications, the proposed method gives improved results. Most of the discrepancies between

the classical TMM and the measurements are explained by the presence of external tonehole interactions.

Generally speaking, Fig. 5 exhibits a major feature of stop bands: external interaction yields a significant reduction of oscillations with frequency, i.e. a reduction of the standing wave amplitude. This feature was stated by Kergomard [13]. In Appendix A, a theoretical justification is given, allowing the following interpretation:

- without interaction, there is reflection at the end, with standing waves inside the lattice;
- without interaction, standing waves imply the existence of extrema of flow rate, the different holes radiating at different levels;
- the holes radiating strongly have an important influence on the holes radiating weakly, thus there is a kind of equalization of radiation by the different holes, thus a diminution of the apparent standing wave ratio (SWR);
- finally at the input of the lattice there is a diminution of the reflection coefficient.

A consequence is the reduced height of the impedance peaks above the cutoff frequency and a reduction in the radiation directivity lobes in the backward direction [13].

4 Results for a Saxophone and a Clarinet

A precise computational FEM model of a complete music instrument is difficult to create and requires significant computation time to solve. Thus, the TMMI model can provide a faster and easier numerical technique which provides satisfactory results for real instruments with complicated geometry, despite the fact that the theoretical description of the toneholes with key pads is overly simplified. In general, we can at least expect that qualitative effects are well represented. Results of the TMM, TMMI, and measurements for an alto saxophone and a clarinet are presented in this section.

4.1 Saxophone

The input impedance of an alto saxophone was measured and compared with calculations using the TMMI and classical TMM methods. The instrument is a Selmer Super Action Series II, serial 438024. The imaginary part of the reflectance and the magnitude of the impedance for the first register Ab_4 , and $C\#_4$ fingerings (respectively 247.0 and 329.6 Hz) are shown in Figs. 6 and 7.

For both fingerings, it appears that the TMMI better matches the experimental results than the TMM. The magnitude of the first three peaks of the impedance curve are reduced by the external interactions and closely match the experimental data. The behavior of the imaginary part of the reflectance is also better predicted by the TMMI.

Figure 6: Imaginary part of the reflectance (left) and magnitude of the impedance (right) of an alto saxophone with a Ab fingering: experimental results (solid) calculations with external interactions (dashed) and calculations with the TMM (dotted).

Figure 7: Imaginary part of the reflectance (left) and magnitude of the impedance (right) of an alto saxophone with a C# fingering: experimental results (solid) calculations with external interactions (dashed) and calculations with the TMM (dotted).

4.2 Clarinet

Similarly to the case of the saxophone, the resonance frequencies of a *Bb* clarinet are predicted to be lower when external interactions are accounted for.

For fingerings where many toneholes are open, the lowering is on the order of 10–15 cents, slightly larger than for the saxophone. Of course, the lowest notes of the instrument, where only a few toneholes are open, are not much affected by this effect.

For higher frequencies, the behavior of the instrument changes significantly. As an example, Fig. 8 displays the imaginary part of the reflectance and the magnitude of the impedance for the fingering A_4 (391 Hz). The resonances correspond to the zeros of the imaginary part of the reflectance when the slope is negative. For the first two resonances, the external interaction only slightly shifts the frequencies to a lower value and the maximum of the impedance corresponds with the zeros of the imaginary part of the reflectance. There are three successive maxima between 1500 Hz and 2000 Hz. The frequencies and magnitudes

Figure 8: Imaginary part of the reflectance (left) and magnitude of the impedance (right) of a clarinet with a A fingering: experimental results (solid) calculations with external interactions (dashed) and calculations with the TMM (dotted).

of these maxima are significantly modified by the external interaction. Notably, the first maxima no longer corresponds to a zero of the imaginary part of the reflectance so that only two resonances exist in this range compared with three when the interactions are accounted for.

5 Conclusion

The aim of this paper was the statement of the TMMI calculation method, comparisons between FEM, TMMI, and TMM methods, and preliminary comparisons with experimental data. Future work needs to be done for a systematic comparison between theory and experiment for the case of woodwind instruments. This is a long and delicate task because it requires very precise geometrical measurements, including bends and positions of the keys over the tone holes, as well as a precise theory. Concerning the TMMI, it would be useful to add internal interaction effects, at least for the determination of the resonance frequencies (notice that these effects do not yield radiation effects, thus dissipative effects, in comparison to the external interactions).

The TMMI method provides a more accurate means for the calculation of the acoustics properties of woodwind instrument because it accounts for external interactions. The discrepancies between the TMMI and FEM are rather small and can probably be explained by several factors: first, the values of the radiation-matrix elements are roughly approximated; second, when several adjacent toneholes are closed, further improvement of the higher frequency modeling of a woodwind instrument would require internal coupling of higher-order modes to be accounted for.

In Appendix A, a modified version of the TMM is investigated. It is based upon a perturbation principle, and could be simpler than the TMMI. Unfortunately, the convergence is limited to pass bands (above the first cutoff). Therefore this method, used by Nederveen et al. [17, p. 115], cannot be used for stop bands.

Finally, we can summarize some effects of the interactions between holes as:

- The effect of tonehole interactions is generally more important when the toneholes are closer together.
- The order of magnitude of the interaction effect seems to be of the same order for saxophones and clarinets.
- At higher frequencies, the high-pass filtering behavior of the tonehole lattice allows more flow past the first tonehole and increases the effect of interactions, particularly near the cutoff frequency.
- Above cutoff, the standing wave ratio is reduced by the effect of interactions.

Appendix A: Is it Possible to Compute the External Interaction by the Transfer Matrix Method?

We consider the equation to be solved:

$$\mathbf{U} = (\mathbf{1} + \mathbf{Y}\mathbf{Z}_R)^{-1}\mathbf{U}_s \quad (23)$$

It is interesting to study if it is possible to solve this equation by perturbation, starting from the TMM method. A quite natural way to do this is to consider that the effect of the external interaction is weak, and to keep a calculation based upon transfer matrices. A first calculation is done without interaction, then the pressures are modified by calculating them with interactions taken into account. The perturbation calculation can be stopped here, but it is possible to iterate it: a new self-impedance is calculated as the ratio of the modified pressure to the unmodified flow rate, then the new flow rates can be calculated again

from the transfer matrix method with the modified values of the self-impedances. In practice, the iteration scheme is found to converge for almost all frequencies except low ones. This result is intuitive because in the stop band, the external sound pressure decreases proportionally to the inverse of the distance, while the internal pressure decreases exponentially, therefore the external interaction is more significant.

It is possible to derive a criterion of convergence for the iteration procedure and, when it converges, it is possible to prove that the result is correct. This is done hereafter. At each step n of the calculation, the transfer matrix method leads to the following relationship between the source \mathbf{U}_s , having a single non-zero element, $U_s(1)$, and the pressure and flow rate vectors, $\mathbf{P}^{(n)}$ and $\mathbf{U}^{(n)}$:

$$\mathbf{U}_s = \mathbf{U}^{(n)} + \mathbf{Y}\mathbf{P}^{(n)}. \quad (24)$$

The calculation is done by defining a diagonal matrix for the termination impedance of each hole (both the direct method and the transfer matrix method can be used):

$$\mathbf{P}^{(n)} = \mathbf{D}^{(n)}\mathbf{U}^{(n)}. \quad (25)$$

From the knowledge of the flow rate $\mathbf{U}^{(n)}$, the next value of the pressure $\mathbf{P}^{(n+1)}$ is deduced:

$$\mathbf{P}^{(n+1)} = \mathbf{Z}_R\mathbf{U}^{(n)}. \quad (26)$$

The iteration equation is therefore found to be, with $\mathbf{M} = \mathbf{Y}\mathbf{Z}_R$:

$$\mathbf{U}^{(n+1)} = \mathbf{U}_s - \mathbf{M}\mathbf{U}^{(n)}. \quad (27)$$

The recurrence relationship leads to the following solution:

$$\mathbf{U}^{(n)} = \left[\sum_{i=0}^{n-1} (-1)^i \mathbf{M}^i \right] \mathbf{U}_s + (-1)^n \mathbf{M}^n \mathbf{U}^{(0)}. \quad (28)$$

If the norm of the matrix \mathbf{M} is less than unity, the recurrence converges to the solution (23), the series corresponding to a Neumann series expansion.

Now the starting point can be discussed. The first idea is to deduce the solution without interaction from the transfer matrix product :

$$\mathbf{U}^{(0)} = (\mathbf{1} + \mathbf{Y}\mathbf{D})^{-1} \mathbf{U}_s, \quad (29)$$

where \mathbf{D} is the diagonal matrix of the self-impedances of \mathbf{Z}_R . Another possibility is to start with $\mathbf{U}^{(0)} = \mathbf{U}_s$: this implies that the first pressure vector is built with the pressures created by a flow rate located at the first open hole. It can be concluded that the transfer matrix method can be used when the norm of the matrix $\mathbf{Y}\mathbf{Z}_R$ is less than unity. Because it can be verified that

this is not true in the stop band, the perturbation method unfortunately cannot be used in general. This confirms the intuition: looking at Fig. 5, it appears that the effect of external interaction can be very large in stop bands for holes very far apart from each other and the perturbation method cannot converge.

Nevertheless, in pass bands we observe that convergence occurs rapidly when starting from Eq. (29), and even the first order, corresponding to a single perturbation step, is satisfactory. This observation thus justifies the reasoning given in Sec. 3.
